Applications of Laplace Transform to Integral Equations and ODEs

Welcome back to series of lecture on Transform calculus and in the last lecture we have evaluated Laplace and inverse Laplace transform of various special function and today some of the function will be used to solve the differential and integral equations. So, what is, go for application and today we will continue with this by solving various kind of differential equations mainly the initial value problems, boundary value problems and also some integral equations and let us see.

(Refer Slide Time: 00:59)

So, I start with the general procedure. So, the general procedure is that first we take the take the Laplace transform both side of the given differential or integral equation **differential or integral equation**. In the second step after taking this Laplace transform, we will get either algebraic equation or ordinary differential equations. In any case we will obtain an equation of the form Laplace of y as a function of s from this transformed differential equation, transformed ordinary differential equation or algebraic equation.

And third step, we will apply the inverse Laplace transform **inverse Laplace transform** to get the solution of the original problem. So, to get as y is Laplace inverse of $F(s)$. So, y is our unknown differential equation. So, there are basically three steps in the; first we take Laplace transform both side of the given differential equation and then from the algebraic equation either we simply that algebraic equation or we solve the ordinary differential equation and we get the Laplace y is equal to function of this s . And then at last we apply the inverse transform and we get the solution of the original problem. So, we will discuss any with the help of various examples today in this lecture and let me just point out here that in the process we assume other solution is continuous and of exponential or because that is very important for the existence of Laplace transform. In fact, if our equation is linear and with constant coefficients then one can prove that solution is some assumption that the solution is continuous and exponential or. So, whatever example here we will consider in all of them we have the continuity in the solution and the solution is of exponential order. So, we can apply this Laplace transform without any problem.

(Refer Slide Time: 04:04)

Initial value Problem:

Solve: $\frac{d^2y}{dt^2} + y = 1$ $y(0) = y'(0) = 0$

Sol: Take L.T.

$$\mathcal{L}\{y''\} + \mathcal{L}\{y\} = \mathcal{L}\{1\}$$

$$\Rightarrow \{s^2 \mathcal{L}\{y\} - s y(0) - y'(0)\} + \mathcal{L}\{y\} = \frac{1}{s}$$

$$\Rightarrow (s^2 + 1) \mathcal{L}\{y\} = \frac{1}{s}$$

$$\Rightarrow \mathcal{L}\{y\} = \frac{1}{s(s^2 + 1)} = \left(\frac{1}{s} - \frac{s}{1 + s^2} \right)$$

Take inverse L.T. $y = 1 - \cos t$

So, let us start with initial value problem **initial value problem**. So, in this problem we want to solve d^2y over dt square plus y is equal to 1 and the given initial conditions are y at 0 and first derivative of y at 0, both are 0. So, very simple initial conditions. So, while solving as first step we take Laplace transform both side of equation. So, we have the Laplace transform of y double prime plus Laplace transform of y and the Laplace

transform of one. By the derivative theorem and that is the point that we can use this initial value problems. So, that this derivative theorem will help. So, here if we apply the derivative theorem we have s^2 and Laplace of y minus $s y(0)$ and minus $y'(0)$ and does see derivative theorem for this and then we have Laplace of y and we have Laplace of one that is one over s .

So, here this term is gone because is 0 and this is also 0. So, we have simply s^2 plus 1 and Laplace of y and this is equal to 1 over s and let me just point out here there is Laplace transform taken actually. This as well suited for solving the initial value problem actually because we have already use this initial value the given initial value use that for this is the best suited for initial value problem. So, here and now we get Laplace transform of y . So, everything as to right hand side. So, we have s and 1 plus s^2 and now we do partial fractions of this. So, we have simply in this case one over s then we have 1 plus s^2 . So, if we have here s simply and minus sign, we will get one over s and 1 plus s^2 and this is trick to get Laplace inverse basically by these partial fractions. So, we have one over s minus s over 1 minus s^2 , the Laplace of y . So, we take the inverse now take inverse Laplace transform and then we will get this y equal to. So, this Laplace inverse of one over s that is, one and we know the Laplace inverse of s over 1 minus s^2 is simply curve T . That is the solution which incorporate automatically the initial conditions because we are using at some point all these initial conditions.

(Refer Slide Time: 07:12)

$$\begin{aligned} \mathcal{L}^{-1}\left\{\frac{1}{s(1+s^2)}\right\} &= 1 * \sin t = \sin t * 1 \\ &= \int_0^t \sin(z) \cdot 1 \cdot dz \\ &= -\cos(z) \Big|_0^t = \underline{\underline{1 - \cos t}} \end{aligned}$$

And solution just one more point that, we have valued from the Laplace inverse of 1 over s 1 plus s square by the partial fraction method that the, I mean we did here partial fraction and then use this Laplace inverse to each fraction to get the Laplace inverse, but, what we can also do that using the convolution theorem we have discuss already in the last lecture. So, this is the convolution of the Laplace inverse of one over s and Laplace inverse of 1 over 1 plus s square. That is, so, this is convolution of 1 over s that is 1 and convolution with this sin t. That is Laplace inverse of 1 plus 1 over 1 plus s square. So, by this symmetric property, we have convolution one and this is nothing our 0 to t, the convolution integral and then we have sin tau and t minus tau. So, this is independent of t. So, we have d tau and sin t whole give as minus this cos tau and then 0 to t. So, we have simply 1 minus cos t same value what we obtain there.

(Refer Slide Time: 08:39)

Ex: Solve:

$$\frac{d^2y}{dt^2} - 6 \frac{dy}{dt} + 9y = t^2 e^{3t}$$

$$y(0) = 2, \quad y'(0) = 6.$$

Sol:

$$s^2 Y(s) - s y(0) - y'(0) - 6 \{ s Y(s) - y(0) \} + 9 Y(s) = \frac{2}{(s-3)^3}$$

$$\Rightarrow Y(s) [s^2 - 6s + 9] = \frac{2}{(s-3)^3} + 2s - 6$$

$$\Rightarrow Y(s) = \frac{2}{(s-3)^3} + \frac{2(s-3)}{(s-3)^2}$$

Taking inverse L.T.

$$y(t) = 2 \cdot \frac{1}{6} t^2 e^{3t} + 2 e^{3t}$$

$$y(t) = \frac{1}{3} t^2 e^{3t} + 2 e^{3t}$$

So, for the next example we solve d^2y over dt square minus 6 dy over dt plus 9 y is equal to t square e^{3t} and initial conditions are $y(0) = 2$ and $y'(0) = 6$. So, slightly more difficult because say the initial values are, both initial values are given in the earlier example was 0. Our equation was much simplified up to taken Laplace transforms. So, here again we do the same steps, we take Laplace transform of this first term d^2y over dt square and that is s square lap place transform of y . We can also denote by this big y s and minus $s y(0)$ minus $y'(0)$ and minus 6. And here we can again use the derivative theorem $s y(s) - y(0)$ and plus 9 and Laplace of y that is $y(s)$ and is equal to here the Laplace of t square e^{3t} . So, use the first shifting property. So, Laplace of t square is 2

over s cube and then we have e power minus $3t$. So, the Laplace will be 2 over s minus 3 cube using the first shifting property. So, now, we collect the terms of this y s . So, what we have? s square from here minus $6s$ and then plus 9 , the right and side we have 2 over s minus 3 cube then $y(0)$ is 2 . So, this $2s$ will go to the right side to give us $2s$. Then here we have 6 and then $y(0)$ is 2 .

So, we have plus 12 and minus 6 . So, we get 6 . So, that side it will be minus 6 . From here we get this y s that is 2 over s minus 3 here if look at this; we have actually s minus 3 whole squares. So, then we take to right hand side here we have s minus 3 power 5 and $2s$ minus 3 over s minus 3 square. So, now, the last step we take the inverse Laplace transform to get the solution and we have $y(t)$ then and this case two. And the Laplace inverse of one over s minus 3 power 5 . So, we have to use again the shifting theorem and that will give us e power $3t$ and this is for $t \geq 1$ over s power 4 s power 5 . So, we have one over factorial 4 , that constant will be moderated here and we have t^4 and e^{3t} for this s minus 3 for shift and similarly, here this is 1 over s minus 3 and that will be e^{3t} . Again the shift theorem alternately one over s minus three we know e^{3t} . So, our solution is then $y(t)$ is. So, here we have 1 over 12 and $t^4 e^{3t}$ plus $2e^{3t}$. So, you get the solution again this incorporates the initial conditions we have. So, this was rather simple differential equation and now we will and that is mean application of this Laplace transform when the right hand side is basically it is continuous function or other complicated function sitting there and there very difficult to solve.

(Refer Slide Time: 13:04)

Ex: Solve $y'' + y = CH(t-a)$
 $y(0) = 0$; $y'(0) = 1$.

L.T:
 $s^2 Y(s) - s y(0) - y'(0) + Y(s) = C \int_a^\infty e^{-st} dt$
 $\Rightarrow (s^2 + 1) Y(s) - 1 = C \cdot \frac{e^{-as}}{s}$
 $\Rightarrow Y(s) = \frac{1}{s^2 + 1} + C \cdot \frac{e^{-as}}{s(s^2 + 1)}$
 I.L.T.
 $\Rightarrow y(t) = \sin t + C \cdot \mathcal{L}^{-1} \left\{ \frac{1}{s(s^2 + 1)} \cdot e^{-as} \right\}$
 $= \sin t + C \cdot \mathcal{L}^{-1} \left\{ \left(\frac{1}{s} - \frac{s}{s^2 + 1} \right) e^{-as} \right\}$
 $y(t) = \sin t + C \cdot H(t-a) \cdot \{ 1 - \cos(t-a) \}$

So, in the next example we will see then the right hand side solve $y'' + y = c$ and heavy side function $t - a$. So, or unit step functions. So, here this constant when t is greater than a some positive and this is 0 and t is less than a . So, the initial conditions is given $y'(0) = 1$. So, again we take the Laplace transform. Both the side of equation $s^2 Y + \text{sorry} - s y(0) - y'(0)$. Here we have $s Y$ Laplace transform of y and then we have c , the Laplace transform of the second write from the basic definition. So, essentially this is defined for the first $0 < t < \infty$ and it will be $e^{-st} dt$. So, what we have here $s^2 + 1$ and we have $y(0) = 0$. So, this term is gone then and $y'(0) = 1$. So, we have -1 here and are equal to c and now if integrate this e^{-st} over $-s$ and as t approaches to infinity for this positive s this will be 0. So, we have e^{-as} / s or we have s^2 . This we have take to right hand side we have $s Y = 1 / (s^2 + 1) + c / (s^2 + 1)$ plus constant and e^{-as} / s and $s^2 + 1$.

Now the last step we have take inverse Laplace transform. So, inverse Laplace transform and that will give us $y(t)$ is equal to this we know that is $\sin t$, the Laplace transform of one over $s^2 + 1$ and we have constant term here. And the Laplace inverse of this one over $s^2 + 1$ and e^{-as} . So, again here, $\sin t$ plus a constant and this second shifting theorem because e^{-as} is there then will be having shift in t . So, what we will get, but, first we need to know what is the Laplace inverse of this function? So, for that we need to first get the partial fraction of this $1 / (s^2 + 1)$ and we have e^{-as} and now we can do this, $\sin t + c$ and this is the shift theorem we will be using here. So, heavy side function $t - a$ will come and Laplace inverse of this $t - a$ instead of t . So, we have here one there is no $t - a$ because Laplace inverse of $1 / s$ is 1 and minus this is $\cos t$, the Laplace inverse $s / (s^2 + 1)$ is $\cos t$, but, we have this shift here. So, we will get $\cos(t - a)$. So, this is the solution of the given initial value problem.

(Refer Slide Time: 17:11)

The image shows a handwritten solution on a blue background. At the top, it states the differential equation: $y'' + 2y' + 2y = \delta(t-3)$ with initial conditions $y(0) = y'(0) = 0$. The solution proceeds by taking the Laplace transform (L.T.) of both sides, resulting in $(s^2 + 2s + 2)Y(s) = e^{-3s}$. This is then rearranged to $Y(s) = \frac{1}{(s+1)^2 + 1} e^{-3s}$. A note indicates that the inverse Laplace transform of $\frac{1}{(s+1)^2 + 1}$ is $e^{-t} \sin t$. Finally, the second shift theorem is applied to yield the solution $y(t) = H(t-3) e^{-(t-3)} \sin(t-3)$.

Now in the next example, we will take even more complicated right hand side of the differential equation and that is y double prime plus two y prime and $2y$ this equal to delta t minus 3. So, this delta function and we can easily solve this equation using the Laplace transform. So, the initial conditions we have y prime 0 y prime y 0 and both 0 just for simplicity and the solution we can see then. So, we apply Laplace transform both sides of the equation. So, we have s square Laplace transform of y minus $s y$ 0 and we have minus y prime 0 plus this 2 again the derivative theorems. So, $s y$ s minus y 0 and plus 2 we have y s and the Laplace transform of this delta function we have discussed in the last lecture that is simply e power minus 3 s . So, what we have now, we collect the coefficients of this y s . So, we have s square, we have 2 s and we have two from there and then y s . This y 0 this is 0 this is also 0 this is also 0. So, we have this all other term 0 and e minus 3 s . So, y s 1 over this we can also write s plus 1 whole square plus 1 and e minus 3 s .

Now, we this we can get using the calculation second shift theorem, but, first we need to get the Laplace transform of this term one over s plus 1 square plus 1 and this again the shifting theorem, the first shifting theorem because s shifted to s plus 1 because this is nothing as for the Laplace transform of $\sin t$, but, we have to use shift theorem for this s plus 1. So, what we have. So, note that the Laplace inverse of this first s plus 1 whole square plus 1 using the first shifting theorem with e power minus t and the Laplace inverse of one over s square plus 1 and that is $\sin t$. So, once we have this Laplace

inverse e power minus t sin t we can get the Laplace inverse of this function with e power minus 3 s using in the second shifting theorem. So, this will give us taking the inverse Laplace transform now of the y s we will get y t and that will give us e power minus t sin t is there and we will get shift in t. So, with h t minus 3 because minus three is there because t minus 3 e power minus t minus 3 and sin t minus 3. With the second shifting theorem, we have this solution when the right hand side is t there delta function. So, these were examples of the initial value problems and now we will go for when the initial conditions are not given in that case also, we can get the general solution for example, we take this.

(Refer Slide Time: 21:01)

Ex: Find the general solution of

$$y'' + y = e^{-t}$$

Sol: $s^2 Y(s) - s y_0 - y_1 + Y(s) = \frac{1}{s+1}$

$$\Rightarrow (s^2 + 1) Y(s) - s y_0 - y_1 = \frac{1}{s+1}$$

$$\Rightarrow Y(s) = \frac{1}{(s+1)(s^2+1)} + \frac{s y_0}{s^2+1} + \frac{y_1}{s^2+1}$$

$$\Rightarrow Y(s) = \frac{1}{2} \left(\frac{1}{s+1} - \frac{s-1}{s^2+1} \right) + \frac{s y_0}{s^2+1} + \frac{y_1}{s^2+1}$$

I.L.T.

$$y(t) = \frac{1}{2} e^{-t} - \frac{1}{2} \cos t + \frac{1}{2} \sin t + y_0 \cos t + y_1 \sin t$$

$$y(t) = \frac{1}{2} e^{-t} + \underbrace{(y_0 - \frac{1}{2})}_{= C_1} \cos t + \underbrace{(y_1 + \frac{1}{2})}_{= C_2} \sin t$$

So, find the general solution **the general solution** of y double prime plus y e power minus t, no initial conditions are applied here. So, we have to get the general solution. So, now, the procedure is same. So, we have to take Laplace transform now. So, s square and y s minus s s y 0 minus y prime 0 and plus y s Laplace of y and Laplace of e power minus t is 1 over s plus 1. So, what we have now here s square plus 1 with this y s minus s. Let us call it y 0, a simple notation now for this we call it y 1 these are the constants and 1 over s plus one. So, instead of given some numerical value we will continue the calculation this y 0 and y 1. This is the only difference and we have then y s is equal to 1 over s plus 1 s square plus 1 plus s y 0 over s square plus 1 plus y 1 over s square plus 1 or y s. Again we do the partial fraction here. So, we have 1 over s plus 1 and s minus 1 over s square plus 1. So, what we have getting here? S square plus 1 minus s square and

plus 1. So, we get 2 here. So, to compensate that we have half and plus $s y' + 0$ over $s^2 + 1$ and plus y over $s^2 + 1$.

Now, we can take the Laplace Trans inverse Laplace transform. So, so inverse Laplace transform will give us now $y(t)$ and this is $\frac{1}{2}$ Laplace inverse of and this is one over two Laplace inverse of linearity property we can apply here. So, one over $s + 1$ that will be e^{-t} then we have again this half here minus half and s over $s^2 + 1$ that is $\cos t$. Then we have Laplace 1 over $s^2 + 1$. So, this is $\sin t$ here again we have $y(0)$ and with this $\cos t$ and we have $y(1)$ and Laplace inverse 1 over $s^2 + 1$ that is $\sin t$. So, we have half e^{-t} and plus $y(0)$ we can combine this two $y(0)$ minus half $\cos t$ and plus this $y(1)$ plus half and $\sin t$ and this $y(0) + 1$ are which constant here $y(0)$ minus half we can put another constant and this we can put another constant. So, this is the general solution of the given differential equation. That is $y(t)$ is half e^{-t} plus some constant with $\cos t$ plus another constant and $\sin t$. So, this was the example we have found the general solution of the differential equation.

(Refer Slide Time: 24:56)

Boundary value problem:

Ex: $y'' + y = \cos t$
 $y(0) = 1$ $y\left(\frac{\pi}{2}\right) = 1$.

Sol: $s^2 Y(s) - s y(0) - y'(0) + Y(s) = \frac{s}{s^2 + 1}$

$\Rightarrow Y(s)(s^2 + 1) = \frac{s}{s^2 + 1} + s + y'(0)$

$\Rightarrow Y(s) = \frac{s}{(s^2 + 1)^2} + \frac{s}{s^2 + 1} + \frac{y'(0)}{s^2 + 1}$

We know $\mathcal{L}\{\cos t\} = \frac{s}{s^2 + 1}$ & $\mathcal{L}\{t \cos t\} = -\frac{d}{ds} \left\{ \frac{s}{s^2 + 1} \right\} = \frac{2s}{(s^2 + 1)^2}$

$\Rightarrow y(t) = \frac{1}{2} t \cos t + \cos t + y'(0) \sin t$

And now we continue for boundary value problem. Instead of initial value problems we have the boundary value problem **boundary value problem**. So, in this case we have $y'' + y = \cos t$ and the conditions are given that $y(0) = 1$ and y at $\pi/2$ is 1. So, we do not have information on the first derivative at 0 instead of that we have the y at $\pi/2$ is 1. So, the procedure is same as the Laplace transform here. So, s

square $y'' - y' + y = 0$ and minus $y'(0) + y(0)$ plus $y''(0)$ Laplace transform of this $y'' - y' + y = 0$ and Laplace transform of $\cos t$. That is s over $s^2 + 1$.

So, we have $y'' - y' + y = 0$ now here and here and. So, with $s^2 + 1$ and we have this $y(0) = 1$ this given that is 1. So, we can use that. So, this will take any way to the right hand side. So, we have s over $s^2 + 1$ we have plus s from here and we have $y'(0)$ which is not known at this moment. So, here we get then the expression from $y'' - y' + y = 0$ this is $s^2 + 1$ whole square plus s over $s^2 + 1$ and plus $y'(0)$ over $s^2 + 1$ and now, we can take the inverse. Before that we let me just point out that where our, we get $s^2 + 1$ whole square type thing. So, because we know that Laplace transform of $\sin t$ is one over $s^2 + 1$. So, we know that the Laplace transform of $\sin t$ that is 1 over $1 + s^2$ and also then Laplace transform of $t \sin t$ by theorem we have this d/ds of the Laplace transform of $\sin t$. That is 1 over $1 + s^2$ and we get simply here get $2s$ over $(s^2 + 1)^2$. So, this is the term which we can see here. So if we take the Laplace inverse transform that $y(t)$ whole be here and the factor will come. So, half $t \sin t$ plus $\cos t$ and here plus $y'(0)$ and then $\sin t$. Now the question is how to get $y'(0)$, but, we have a condition here that $y(\pi/2) = 1$. So, we can use that condition get this $y'(0)$.

(Refer Slide Time: 28:09)

Using $y(\frac{\pi}{2}) = 1$:

$$y(\frac{\pi}{2}) = 1 = \frac{1}{2} \cdot \frac{\pi}{2} \sin(\frac{\pi}{2}) + \cos(\frac{\pi}{2}) + y'(0) \sin(\frac{\pi}{2})$$

$$\Rightarrow 1 = \frac{\pi}{4} + y'(0) \Rightarrow y'(0) = (1 - \frac{\pi}{4})$$

$$y(t) = \frac{1}{2} t \sin t + \cos t + (1 - \frac{\pi}{4}) \sin t$$

So, using the given boundary condition $y(\pi/2) = 1$ we can have here $y(\pi/2) = 1$ and then half t . So, we have this solution again $t \sin t$. So, we will get here $\pi/2$ and

$\sin \pi$ by 2 plus $\cos \pi$ by 2 from this and then $y'(0) \sin t$. So, plus $y'(0)$ and $\sin t$ $\sin \pi$ by 2. So, what we get here? One then we have π by 4, this is 1 this is 0 and plus then $y'(0)$ this is also 1. So, here we get $y'(0)$ is 1 minus π by 4 that we can again substitute to get that $y(t)$ is $\frac{1}{2} t \sin t + \cos t + 1 - \frac{\pi}{4} \sin t$. So, in this way we can also obtain the solution of the boundary value problem. Now, the next category we will move and here up to know we have the linear equation with constant coefficients. So, now, we will consider the differential equations when the constant of derivative terms are not constant, but, they are the polynomials.

(Refer Slide Time: 29:43)

Ex: Solve $y'' + ty' - 2y = 4$;
 $y(0) = -1$ $y'(0) = 0$

Sol: Taking L.T.:
 $s^2 Y(s) - s y(0) - y'(0) + \left(-\frac{d}{ds}\right) \{s y(s)\} - 2 Y(s) = \frac{4}{s}$
 $\Rightarrow s^2 Y(s) + s - \frac{d}{ds} \{s Y(s)\} - 2 Y(s) = \frac{4}{s}$
 $\Rightarrow s^2 Y(s) + s - s \frac{dY}{ds} - Y(s) - 2 Y(s) = \frac{4}{s}$
 $\Rightarrow (s^2 - 3) Y(s) - s \frac{dY}{ds} = \frac{4}{s} - s$
 $\Rightarrow \frac{dY}{ds} + \left(\frac{3-s}{s}\right) Y(s) = -\frac{4}{s^2} + 1$

So, for example, solve this $y'' + ty' - 2y = 4$ and the initial conditions are given that $y(0)$ is minus 1 and $y'(0)$ is 0. So, here this term, the coefficients are not constant any more, but, they are polynomial in t . The procedure is same, but, now this time we will get the ordinary differential equation rather than the simple algebraic equation. So, taking Laplace transform both sides what we get here? $s^2 y$ Laplace transform of y minus $s y(0)$ and minus $y'(0)$ plus the Laplace of ty' that is again the theorem we use when we multiplication by t . So, d over ds and the Laplace transform of y' minus 2 Laplace transform of y and 4 Laplace transform of 1. So, 4 over s . So, it we have now?

First let us do this, $ys - s$ and $y(0)$ is minus 1. So, we will get plus s this is 0. So, we have minus d over ds of d over s of Laplace of y' . So, that is $ys - s$ minus $y(0)$ by

the derivative theorem $2y + s^4$ over s . So, $s^2 y + s$ minus we differentiate here as product. So, d over ds we will get $s \frac{dy}{ds}$ and will get minus $y + s$ here it is a constant term. So, d over ds will make it 0 and $2y + s$ we have 4 over s . So, we take common this $y + s$ here also $2y + s$. So, we have s^2 minus three with $y + s$ and then we have minus $s \frac{dy}{ds}$ we have right hand side 4 over s and we have this take to the minus s to the right side. So, what we have? The equation $d y$ over ds ordinary differential equation plus 3 minus s because 1 minus sign will accommodate this 3 over s and minus s we have $y + s$ and is equal to dividing by this s . So, we have 4 over and multiplying this minus sign. So, 4 over s^2 and plus 1 **plus 1**. Now, this is the ordinary differential equation linear equation.

(Refer Slide Time: 33:16)

The image shows a handwritten derivation on a blue background. It starts with the calculation of an integrating factor (IF) as $e^{\int (\frac{3}{s} - 1) ds} = e^{3 \ln s - \frac{s^2}{2}} = s^3 e^{-s^2/2}$. Then, it solves the differential equation $y(s) \cdot s^3 e^{-s^2/2} = \int (-\frac{4}{s^2} + 1) s^3 e^{-s^2/2} ds + C$. The integral is split into two parts: $-4 \int s e^{-s^2/2} ds + \int s^3 e^{-s^2/2} ds + C$. The first integral is $4 e^{-s^2/2}$ and the second is $s^2 e^{-s^2/2} + 2 \int s e^{-s^2/2} ds + C$. This leads to $4 e^{-s^2/2} - s^2 e^{-s^2/2} - 2 e^{-s^2/2} + C$. Finally, $y(s) s^3 e^{s^2/2} = 2 e^{-s^2/2} - s^2 e^{-s^2/2} + C$ and $y(s) = \frac{2}{s^3} - \frac{1}{s} + (C/s^3) e^{s^2/2}$. A boundary condition $\lim_{s \rightarrow \infty} y(s) = 0$ is used to conclude $C = 0$.

So, we will solve this. So, we get integrating factor **integrating factor** that will be e over e power 3 over s minus $s \frac{d}{ds}$ and this is just e power minus s . So, 3 over $s \log s + 3 \ln s$ minus s^2 by 2 . So, this is here we can again simplify this will be just s^3 and e minus s^2 by 2 . So, the solution of that ordinary differential equation in $y + s$ will be $y + s$ integrating factor e minus s^2 by 2 , the integral and right hand side that we have here $-4s^2 + 1$. So, -4 over $s^2 + 1$, this integrating factor e minus s^2 by 2 ds and a constant of integration. So, integrate this. So, we have -4 , this you multiply, we have $s e$ minus s^2 by 2 the first term then we have $+ s^3 e$ minus s^2 by 2 ds and a constant. So, this we can integrate because this differentiation of this is sitting here with minus sign we will adjust at this

place. So, this is nothing else but four and e minus s square by 2 minus. Now, here we have to integrate by parts. So, this one will adjust s e power minus s square by 2 to get this integral. So, we have minus this s square the integration of s e minus s square by 2 will be e minus s square by 2 with minus sign that is here and then minus and then minus will come from that place. So, we have plus and we have 2 s the differentiation of this s square and again the integral of s e power minus s square by 2 will give minus and that is adjusted here. So, here that we have s square by 2 and d s plus c. So, 4 e minus s square by 2 minus s square e minus s square by 2 and we have this state now again.

So, we have minus 2 and this minus d 2, the integral will come with minus and then e minus s square by 2 and plus c. Now, this **this** will give us 2 e minus s square by 2 and we have minus s square e minus s square by two plus a constant. So, this is with y s and s 3 e minus square by 2. So, we get from here y s **y s** is equal to 2 over s cube **2 over s cube** minus one over s and plus this c over s cube and e s square by 2. Now, again we see this one constant here. So, what will happen to this constant? We have already use our initial conditions. Here there is a point that this y s that is the Laplace transform of this y and this as a property as this is the Laplace transform of y s and exponential of function s as s approaches to infinity this must go to 0. As limit s approaches to infinity this s goes to infinity this y as must go to 0 and this is only possible if we see here e power s square by 2 sitting. If s approaches to infinity this term will blow up and then we cannot get the 0 as. So, this is possible only 1 c is 0. So, due to this condition we have that c must be 0. So, c must be 0.

(Refer Slide Time: 38:00)

$$Y(s) = \frac{2}{s^3} - \frac{1}{s}$$

I.L.T. $y(t) = t^2 - 1$

So, this term as gone then. Then we have y s this 2 over s cube minus s . Now, we take the inverse Laplace transform to get y t and this is Laplace transform 2 over s 3. There are simply t square and we have minus 1 this is the answer.

(Refer Slide Time: 38:31)

Ex: Solve: $ty'' + y' + ty = 0$;
 $y(0) = 1$ $y'(0) = 0$.

Sol: L.T.

$$-\frac{d}{ds} \{s^2 Y(s)\} + sY(s) - 1 - \frac{d}{ds} \{Y(s)\} = 0$$
$$\Rightarrow -\frac{d}{ds} \{s^2 Y(s) - 1\} + sY(s) - 1 - \frac{dY}{ds} = 0$$
$$\Rightarrow -\frac{d}{ds} \{s^2 Y(s) - 1\} + sY(s) - 1 - \frac{dY}{ds} = 0$$
$$\Rightarrow -s^2 \frac{dY}{ds} - 2sY(s) + 1 + sY(s) - 1 - \frac{dY}{ds} = 0$$
$$\Rightarrow (1+s^2) \frac{dY}{ds} + sY(s) = 0$$

So, we take another example of a similar kind. So, we have to solve $t y'' + y' + t y$ here also variable coefficients and this $y(0)$ is 1 and $y'(0)$ is 0. Solution again; we take the Laplace transform. So, Laplace transform of this because of this t sitting. So, we have minus d over $d s$ by the property of Laplace transform and the

Laplace over y'' plus the Laplace of y' minus again d over $d s$ and the Laplace of y , this is 0. So, minus d over $d s$ and we have here s^2 Laplace of y minus $s y(0)$ minus $y'(0)$ plus $s y s$ minus $y(0)$ and we have minus d over $d s$ and we denote it by $y s$ and is equal to 0. What we get here $y'(0)$ is 0. So, this term will vanish. So, we have minus d over $d s^2$ $y s$ minus $y(0)$ is 1 plus $s y s$ minus $y(0)$ is 1 plus $s y s$ minus $y(0)$ is 1 minus $d y$ over $d s$ is equal to 0.

So, we simplify this minus $s^2 d y$ over $d s$ minus $2 s y s$ and here we will get d over $d s$ of s^2 . So, minus, minus plus. So, 1 plus 1 plus $s y s$ minus 1 minus $d y$ over $d s$ is equal to 0. So, we collect this terms of $d y$ over $d s$. We have 1 plus s^2 that is multiply with minus sign so $d y$ over $d s$. Then here, we have minus $s y s$. So, $s y s$ multiplied by minus 1 and this is any way they cancel each other and then we have is equal to 0.

(Refer Slide Time: 41:09)

$$\frac{dy(s)}{ds} = -\frac{s}{1+s^2} \frac{y(s)}{s} \Rightarrow \ln y(s) = -\frac{1}{2} \ln(1+s^2) + \ln C$$

$$\Rightarrow \ln y(s) = \ln \left(\frac{C}{\sqrt{1+s^2}} \right)$$

$$\Rightarrow y(s) = \frac{C}{\sqrt{1+s^2}} \Rightarrow y(t) = C \cdot J_0(t)$$

$$y(0) = 1$$

$$1 = C \underbrace{J_0(0)}_{=1} \Rightarrow C = 1$$

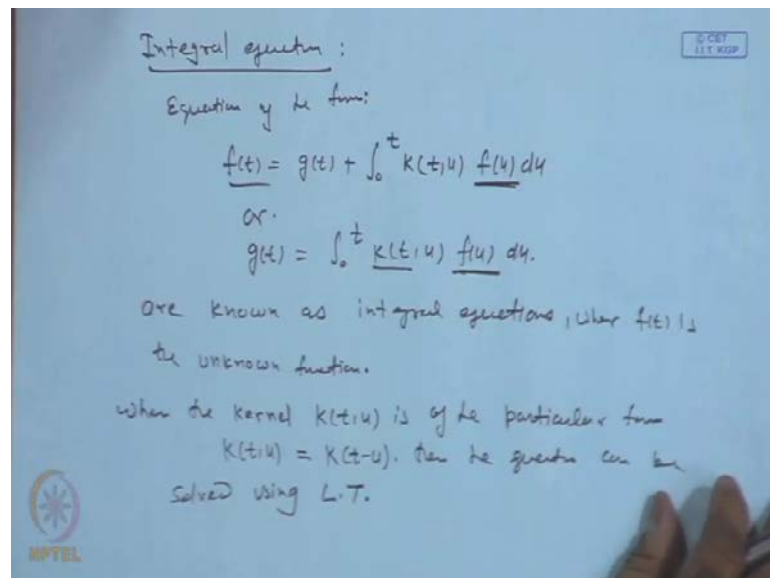

$$J_0(t) = \sum_{r=0}^{\infty} (-1)^r \left(\frac{t}{2}\right)^{2r} \frac{1}{(r!)^2}$$

Solution: $y(t) = J_0(t)$

So, what we get the differential equation is $d y s$ over $d s$ is equal to minus s over 1 plus s^2 $y s$ and this we can easily solve take this to the right hand side to the left hand side in the denominator. So, if we integrate that, we get $\ln y s$ is equal to here we will get this the differentiation is sitting there. So, with minus half and this $\ln 1$ plus s^2 and constant $\ln c$ in this form because we will get rather simple form here. Then, $\ln c$ and divided by this square root of 1 plus s^2 . So, c over 1 plus s^2 square root and here we have $\ln y s$. So, in this way we get $y s$. This is c over one plus s^2 and if we

take the inverse Laplace transform. So, we will get $y(t)$ and in the last lecture we have seen in the Laplace inverse of $\frac{1}{1+s^2}$. That was best of function such as $\sin t$. So, what we have now? **Now**, we have the initial conditions are because this c appears now. So, what we can use at least that $y(0)$ is 1 that is given. So, here we have $y(0)$. So, we have $1/c$ and $y(0) = 1$ and $y(0) = 1$ we know that is one and in this way c we get is equal to one because remember this $y(t)$ was t was the series $\frac{t^{n-1}}{(n-1)!}$ by $\frac{1}{s^n}$ over factorial n whole square. So, the first term will be one and then all other term t appears as this is $y(0)$ will be one. So, we have $c = 1$. So, then the solution of that given differential equation is $y(t) = \sin t$. So, that was the differential equation with variable coefficients and now we come to the integral equation.

(Refer Slide Time: 43:52)

So, the integral equation here also we can apply the Laplace transform to get the solution. So, integral equation. So, equation of the form **equation of the form** $f(t)$ is equal to $g(t)$ plus $\int_0^t k(t,u) f(u) du$ or we can have other form $g(t)$ is equal to $\int_0^t k(t,u) f(u) du$, these equations are known as integral equations **integral equations** where $f(t)$ is the unknown function. So, here this $f(t)$ is unknown, here $f(t)$ is unknown. So, there is a special situation that when the kernel, that is called the kernel of integration, if this kernel $k(t,u)$ is of the particular form **is of the particular form** that this $k(t,u)$ is just function of $t - u$ then, the equation can be solved using the Laplace transform and we will see y because it will be simplify that integral which appears integral equations.

(Refer Slide Time: 45:47)

Ex: Solve.

$$f(t) = e^{-t} + \int_0^t \sin(t-u) f(u) du.$$

Sol:

L.T.

$$\mathcal{L}\{f(t)\} = \frac{1}{s+1} + \mathcal{L}\{\sin t\} \cdot \mathcal{L}\{f(t)\}.$$

$$\Rightarrow \mathcal{L}\{f(t)\} \left[1 - \frac{1}{s^2+1}\right] = \frac{1}{s+1}$$

$$\Rightarrow \mathcal{L}\{f(t)\} = \frac{(s^2+1)}{s^2(s+1)} = \frac{2}{s+1} + \frac{1}{s^2} - \frac{1}{s}$$

$$\Rightarrow f(t) = 2e^{-t} + t - 1$$

So, if we want to solve the integral equation $f(t) = e^{-t} + \int_0^t \sin(t-u) f(u) du$; Solution: so, if we have apply the Laplace transform to this equation we will get the Laplace transform of this $f(t)$ the Laplace transform of e^{-t} . This is as e^{-t} no t square. So, e^{-t} this Laplace transform is $1/(s+1)$ and plus. So, now, if we see this is the convolution integral. So, convolution of this $\sin t$ $f(t)$, so, if we take the Laplace of this convolution to will be just Laplace of the product. So, the Laplace of $\sin t$ and Laplace of $f(t)$ by the Convolutional theorem and this is the point here. Now, it gets simplified. So, we take the Laplace transform $f(t)$ then Laplace transform of $f(t)$ and we have $1 - 1/(s^2+1)$ this Laplace transform of $\sin t$ we know $1/(s^2+1)$ and we have $1/(s+1)$ right hand side.

So, we get Laplace of $f(t)$ is equal to $(s^2+1)/(s^2(s+1))$ this is nothing else right hand side we can take $(s^2+1)/(s^2)$ and $1/(s+1)$. Again, the partial fraction so, this step I skip. So, we have $2/(s+1) + 1/s^2 - 1/s$. Now, we can take the Laplace inverse. So, we have $2e^{-t} + t - 1$ that is $2e^{-t} + t - 1$. So, this is the solution of that integral equation. Now, consider a different example when we will see the integral term as well as differential term. That is called integral differential equation.

(Refer Slide Time: 48:31)

The image shows a handwritten solution on a blue background. It starts with an example: $\frac{dy}{dt} + 4y + 13 \int_0^t y(u) du = 3e^{-2t} + \sin 3t$ with the initial condition $y(0) = 3$. The solution uses the Laplace Transform (L.T.) to convert the differential equation into an algebraic equation in the s-domain: $sY(s) - y(0) + 4Y(s) + \frac{13}{s}Y(s) = 3 \cdot \frac{2}{(s+2)^2+9}$. This is simplified to $(\frac{s^2+4s+13}{s})Y(s) = \frac{9}{(s+2)^2+9} + 3$. The solution for Y(s) is $Y(s) = \frac{9s}{[(s+2)^2+9]^2} + \frac{3}{[(s+2)^2+9]}$. Finally, the inverse Laplace transform is applied to get $y(t) = e^{-2t} \mathcal{L}^{-1} \left\{ \frac{9(s-2)}{(s^2+9)^2} + \frac{3}{s^2+9} \right\}$.

So, we take one example just for the make the concept clear. So, we have here the integral differential equation $\frac{dy}{dt} + 4y + 13 \int_0^t y(u) du = 3e^{-2t} + \sin 3t$ and $y(0) = 3$. This is $3e^{-2t} + \sin 3t$ and $y(0) = 3$ because its differential term appears. So, we have to have the initial condition that is $y(0) = 3$. So, now, we go along with same step. So, we have Laplace transform. So, here s the Laplace transform of y and minus $y(0)$ plus this 4 Laplace transform of y and plus 13 and Laplace transform of this integral and that is just the, $\frac{1}{s}$ and Laplace transform of this y . That was the property will discuss and Laplace transform then we have 3 and then we have the first shift property e^{-2t} and $\sin 3t$ for $\sin 3t$ the Laplace transform is $\frac{3}{s^2+9}$. But, we have shifted here.

So, we have $\frac{3}{(s+2)^2+9}$ and s plus 2 instead of s because of e^{-2t} s^2+9 now we collect the terms of this y s over s is here s^2 and then we have also $4s$ and then we have 13 we have over s we have y s and this $y(0) = 3$. So, we can take to the right hand side which we have $(s+2)^2+9$ and plus plus we have this $y(0) = 3$. So, we simplify this to get y s will be $9s$ and this is again the same term because this is $(s+2)^2+9$. So, we have 4 and then 9 . So, it is the same term. So, we get basically $(s+2)^2+9$ and this square and plus we have 3 over $(s+2)^2+9$. Now, we take the inverse Laplace transform and just remember again the shift property because s is $s+2$. So, let us apply shift property we get e^{-2t} and Laplace inverse of $\frac{9(s-2)}{(s^2+9)^2} + \frac{3}{s^2+9}$ whole square

plus 3 over s square plus 9. So, s is now s minus 1. So, we have s square s minus 2 and we have s square plus 9.

(Refer Slide Time: 51:51)

$$\begin{aligned} \mathcal{L}\{t \sin at\} &= \frac{2as}{(s^2 + a^2)^2} \\ \mathcal{L}\{t \cos at\} &= \frac{s^2 - a^2}{(s^2 + a^2)^2} \\ Y(s) &= e^{-2t} \mathcal{L}^{-1} \left[\frac{9s}{(s^2 + 9)^2} - \frac{18}{(s^2 + 9)^2} + \frac{3}{s^2 + 9} \right] \\ &= e^{-2t} \mathcal{L}^{-1} \left[\frac{9s}{s^2 + 9} + \frac{s^2 - 9}{(s^2 + 9)^2} + \frac{2}{s^2 + 9} \right] \\ &= e^{-2t} \left[\frac{3}{2} \sin 3t + t \cos 3t + \frac{2}{3} \sin 3t \right] \end{aligned}$$

Now, to get this Laplace inverse we should note that the Laplace transform of $t \sin a t$ is $\frac{2as}{s^2 + a^2}$ and the Laplace transform of $t \cos a t$ is $\frac{s^2 - a^2}{s^2 + a^2}$. Similarly, the Laplace transform of $t \sin a t$ is $\frac{2as}{s^2 + a^2}$ and the Laplace transform of $t \cos a t$ is $\frac{s^2 - a^2}{s^2 + a^2}$. So, we have that y is e^{-2t} and the Laplace inverse of $\frac{9s}{s^2 + 9}$ is $\frac{3}{2} \sin 3t$. We have $\frac{1}{s^2 + 9}$ and we have $\frac{2}{s^2 + 9}$. So, we have $\frac{1}{s^2 + 9}$ and we need to have $\frac{1}{s^2 + 9}$ here. So, we have $\frac{1}{s^2 + 9}$ and we will take $\frac{1}{s^2 + 9}$ and we will combine with s and what you will get because $\frac{1}{s^2 + 9}$ will be $\frac{s}{s^2 + 9}$ by $\frac{1}{s^2 + 9}$ whole square. So, we will get simply $\frac{s^2 - 9}{s^2 + 9}$ and plus this $\frac{2}{s^2 + 9}$ because $\frac{1}{s^2 + 9}$, we have combined with this term. So, we get e^{-2t} and the inverse of this is easy now is $\frac{2}{3} \sin 3t$ over $s^2 + 9$ by $\frac{2}{3}$. So, this is simply $\frac{2}{3} \sin 3t$. Here we get $t \cos 3t$ and here we get $\frac{3}{2} \sin 3t$. So, this is the solution. The last example we consider quickly and simultaneous differential equation. I will just give the idea how to solve simultaneous differential equation.

(Refer Slide Time: 54:11)

$$\text{Ex: } \frac{dx}{dt} = 2x - 3y \quad \frac{dy}{dt} = y - 2x$$

$$x(0) = 8 \quad y(0) = 3.$$

$$\text{Sol: } sX(s) - x(0) = 2X(s) - 3Y(s)$$

$$\text{and } sY(s) - y(0) = Y(s) - 2X(s)$$

$$\Rightarrow \begin{cases} (s-2)X(s) + 3Y(s) = 8 & \text{--- (1)} \\ 2X(s) + (s-1)Y(s) = 3 & \text{--- (2)} \end{cases} \Rightarrow \begin{cases} X(s) = \frac{8s-17}{(s-4)(s+1)} \\ Y(s) = \frac{3s-22}{(s+1)(s-4)} \end{cases}$$

$$\text{--- (LT): } \begin{cases} x(t) = 5e^{-t} + 3e^{4t} \\ y(t) = 5e^{-t} - 2e^{4t} \end{cases}$$

So, in this example we take very simple example; $\frac{dx}{dt} = 2x - 3y$ and we have $\frac{dy}{dt} = y - 2x$ and the initial conditions must be given that $x(0) = 8$ and $y(0) = 3$. So, what we do? The same steps; we take the Laplace transform of this two equations. We take Laplace transform this equation with denote by $sX(s) - x(0) = 2X(s) - 3Y(s)$ and for the second equation we have, $sY(s) - y(0) = Y(s) - 2X(s)$. So, now, from the first equation we have $sX(s) - 8 = 2X(s) - 3Y(s)$ we will take to the right hand side and this $3Y(s)$ and then we have eight. Let us call it equation one and from this equation we will get this $(s-2)X(s) + 3Y(s) = 8$, this $(s-2)X(s)$ and is equal to $8 - 3Y(s)$. That is equation number two now we need to solve the 2 equations and I will skip that step is very easy here we multiply by $(s-1)$. So, example multiply by 3 then we can cancel this $3Y(s)$ as term we can eliminate this $3Y(s)$ we can get this $(s-2)(s-1)X(s) + 3(s-1)Y(s) = 8(s-1) - 3(s-1)Y(s)$ and we get this $(s-2)(s-1)X(s) = 8(s-1) - 3(s-1)Y(s)$ and we get this $X(s) = \frac{8(s-1) - 3(s-1)Y(s)}{(s-2)(s-1)}$ and we get this $X(s) = \frac{8s-8-3s+3}{(s-2)(s-1)}$ and we get this $X(s) = \frac{5s-5}{(s-2)(s-1)}$ and we get this $X(s) = \frac{5(s-1)}{(s-2)(s-1)}$ and we get this $X(s) = \frac{5}{s-2}$ and we get this $x(t) = 5e^{-t} + 3e^{4t}$.

And now we can take the inverse Laplace transform of in both cases again the partial fractions we have to do and we will get straight away $5e^{-t} + 3e^{4t}$ and this $y(t)$ we will get $5e^{-t} - 2e^{4t}$. So, it was just **just** an idea how to solve this, how to apply this Laplace transforms for system of equation and now I conclude this lecture. So, in this lecture we have seen that how we can apply this Laplace transform various kind of differential equations and we have mainly discuss the various initial value problems, boundary value problems, how to find general solutions and then

integral equations; also for the integral differential equation and at last system of differential equations. So, in and the next lecture we will apply we continue the idea for solving the partial differential equations and that is all for today's. Thank you. Good bye.
